Received February 21, 1996

A calcium oxalate (whewellite)-rich crust occurs on exposed limestone surfaces in dry rock and open air shelters in the Lower Pecos region of southwest Texas. The crust, which also contains gypsum and clay, formed over silica-rich limestone during the Holocene. SEM and optical photomicrographs reveal similarities between whewellite microstructures and the lichen *Aspicilia calcarea*. This desert lichen is known to produce calcium oxalate, and has been found in several sites in the region. The ubiquity of the whewellite-rich crust in the Lower Pecos shelters suggests that the lichen flourished in the past. Since *A. calcarea* is a desert species, the virulence of the organism likely peaked during xeric climate episodes then waned during mesic periods. Thus, radiocarbon ages of whewellite would correspond to dry climate periods experienced in the region, while periods with few or no  $^{14}\text{C}$  data would indicate wet climate episodes. A preliminary paleoclimate reconstruction based on fourteen AMS  $^{14}\text{C}$  dates indicates the Lower Pecos experienced dry to wet climate fluctuations during the late Holocene. This reconstruction generally agrees with other models established for Texas. © 1996 University of Washington.

## INTRODUCTION

Whewellite ( $\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$ ) is the primary constituent of a rock crust that occurs inside dry rock and open air shelters in the Lower Pecos region of southwestern Texas (Russ *et al.*, 1994, 1995). Whewellite, and the polyhydrate weddellite, were

generally considered rare in geological environments (Graustein *et al.*, 1977; Žák and Skála, 1993), but are now known to be common components in natural rock accretions (Del Monte and Sabbioni, 1987; Del Monte *et al.*, 1987; Watchman, 1990, 1991; Edwards *et al.*, 1991; Scott and Hyder 1993; Chaffee *et al.*, 1994; Watchman *et al.*, 1995). Evidence indicates that some oxalate-rich crusts are produced by lichens (Del Monte and Sabbioni, 1987; Del Monte *et al.*, 1987; Russ *et al.*, 1995), although other biological and nonbiological mechanisms have also been proposed (Lazzarini and Salvadori, 1989; Watchman, 1990, 1991).

Characteristics of rock crusts are known to reflect the time frame and climate conditions present when they formed, and thus provide archaeological, geological, and paleoclimate information. For example, Dorn and his colleagues developed experimental methods for dating petroglyphs (e.g., Dorn and Whitley 1983) and geological events (Dorn *et al.*, 1987; Dorn *et al.*, 1987), and for establishing paleoenvironmental conditions (Dorn and DeNiro, 1985) based on properties of rock varnish. Watchman (1993) demonstrated the great antiquity of some Australian rock art by radiocarbon dating laminae of oxalate-rich crusts associated with a prehistoric rock painting. Also, Dragovich (1988) proposed paleoclimate changes using radiocarbon ages of calcium carbonate from carbonate-varnish stratification. We describe here the origin of a whewellite-rich rock accretion in the

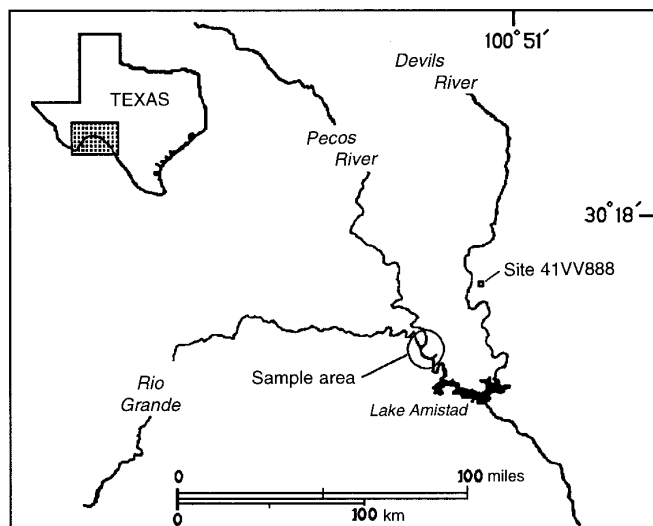

FIG. 1. Map showing the geographical location of the study area.

Lower Pecos region of Texas and propose its use as a paleoclimate indicator.

### STUDY AREA

This study focuses on the rock crust that occurs in sheltered areas in the limestone cliffs along the lower Pecos River, the Rio Grande near the Pecos confluence, and canyon tributaries of the two rivers (Fig. 1). One sample (888-1) from a dry canyon near the Devils River was also included. The Lower Pecos region contains an extensive, nearly continuous archaeological record dating back more than 10,000 yr (Turpin, 1982; Hester, 1983, 1988) and is well known for extraordinary pictograph panels found at more than 250 sites. Rock art interpretation (Turpin, 1990) and  $^{14}\text{C}$  dating (Russ *et al.*, 1990, 1992; Ilger *et al.*, 1995) indicate that the oldest pictograph style, the Pecos River style, was produced between 4200 and 2950 yr B.P.

The Lower Pecos region is at the southwestern edge of the Edwards Plateau and is characterized by Cretaceous limestone, with deep canyons incised by the major rivers and their tributaries. Along the steep canyon walls are numerous dry rock shelters and rock overhangs. Exposed limestone in the canyons is covered with two distinct rock patinas: a dark-grey to black stain coats areas that receive direct rain and runoff, while a light-brown, whewellite-rich accretion covers surfaces inside sheltered areas. Because most pictographs occur in dry rock and open air shelters, the prehistoric paints are almost always associated with the whewellite-rich crust.

The present climate is semi-arid, with a mean annual rainfall of 498 mm/yr. Mean annual temperature is 20.5°C, while

annual mean maximum and minimum temperatures are 27.0 and 13.9°C, respectively.<sup>1</sup>

### EXPERIMENTAL METHODS

Rock crust samples attached to the limestone substrate were collected from vertical or near vertical walls in rock shelters and under rock overhangs. Sampled areas were generally random within each site and away from painted areas, although paint samples from Pecos River style pictographs were included in this study. *Aspicilia calcarea* (identified by J. Marsh, personal communication, 1994), a lichen with a white surface deposit (pruina), was found in two shelters and collected for this study.

The mineralogy of the crust was established using powder X-ray diffractometry (XRD). Samples were prepared by removing the crust from the substrate with a minidrill, then grinding to a powder using an agate mortar and pestle. We removed the entire thickness of the crust and a small part of the substrate to ensure that all of the crust was analyzed. The mineral distribution and external features of the crust were established using an optical microscope and a Jeol 6400 scanning electron microscope equipped with an energy dispersive X-ray analyzer (SEM/EDS). Polished thin-sections and broken sections of the crust and lichen *A. calcarea* attached to 1-cm aluminum stubs were studied.

Twelve samples from nine sites were radiocarbon dated by accelerator mass spectrometry (AMS). Ten of the samples showed a single layer of crust which was completely removed for the radiocarbon analysis. Two samples (128-7 and 129-1) showed two whewellite laminae which were removed and dated separately. A paint layer also observed in the lower whewellite lamina of sample 129-1 was included in the dated material. The amount of organic carbon from the paint was expected to be much less than 1% of the datable carbon (Russ *et al.*, 1992; Ilger *et al.*, 1995).

Samples prepared for  $^{14}\text{C}$  dating first had loose detritus removed by light scrubbing of the crust surface with deionized water and drying at 100°C. While observing with a binocular microscope, 10 to 20 cm<sup>2</sup> of the crust was removed from the substrate using a minidrill. The crust material was ground with an agate mortar and pestle and digested in 5% double distilled acetic acid for 2 days to remove carbonates and sulfates. The samples were thoroughly washed using double distilled water to remove acetic acid, then filtered and dried at 100°C. Each sample was combusted at 950°C in the presence of CuO to produce CO<sub>2</sub>, which was then reduced to graphite with H<sub>2</sub> at 550°C in the presence of a cobalt catalyst. The graphite was submitted for radiocarbon dating to the Center for Accelerator Mass Spectrometry

<sup>1</sup> Data from National Oceanic and Atmospheric Administration Amistad Dam station from 1965 to 1994.

(CAMS) at Lawrence Livermore National Laboratories. When sufficient sample remained, a second aliquot was combusted at 950°C in the presence of CuO and the stable carbon isotope ratio ( $\delta^{13}\text{C}_{\text{PDB}}$ ) of the resulting  $\text{CO}_2$  measured on a Micromass 903 isotope ratio mass spectrometer (Boutton, 1991). Precision on  $\delta^{13}\text{C}_{\text{PDB}}$  values was 0.1‰.

Calcium oxalate control samples for radiocarbon analysis were prepared from solutions of NBS standard  $^{14}\text{C}$  oxalic acid and calcium chloride hydrate (99.99+%) by mixing the solutions and filtering out the calcium oxalate precipitant. The control was divided into three samples, two of which were processed in the acetic acid solution, washed, and dried, while the other remained untreated. The three calcium oxalate controls were then processed for radiocarbon analysis.

## RESULTS

### *Description of the Crust*

The whewellite-rich rock crust appears very pale brown (10 YR 7/4; Munsell Soil Color Charts, 1994) to reddish brown (5 YR 4/4), generally with an irregular surface that has botryoidal and spherical protuberances extending about 0.5 mm above the surface (Fig. 2A). The morphology of these surface features resembles the surface of *Aspicilia calcarea* (Fig. 2B). The crust is thin, usually less than 0.5 mm thick but up to 1.0 mm thick, with most samples showing a single layer of crust, although several had distinct stratification. Pictograph samples have a thin ( $\sim 0.1$  mm), continuous layer of paint encapsulated within the crust. The paint layers did not appear disrupted, even when occurring near the bottom of the crust.

Whewellite, gypsum, quartz, and calcite were the principal minerals identified using XRD (Table 1). Two-dimensional elemental dot maps of polished thin sections showed silicon (quartz) nonuniformly distributed within the limestone substrate, while sulfur (gypsum) occurred primarily in the crust as well as in pore and fissure spaces in the substrate. The crust is composed of microcrystalline whewellite, with tabular gypsum occurring as layers and intrusions into the whewellite phase. Whewellite microstructures resembling the thallus of *A. calcarea* were observed in cross-sectioned views using SEM (Fig. 3). The crust also contained traces of clay, as indicated by aluminum and silicon peaks in EDS spectra, but no clay particles were observed using SEM. Evidence of microorganisms in crust samples were rarely observed, although Kaluarachchi (1995, p. 67) noted what appeared to be cocci bacteria in one of five Lower Pecos paint samples studied using SEM.

### *Description of Aspicilia calcarea*

The lichen *A. calcarea* was  $\sim 0.2$  mm thick and covered throughout with small ( $\sim 1$   $\mu\text{m}$ ) calcium oxalate crystals. XRD analysis of the lichen pruina indicated that weddellite

( $\text{CaC}_2\text{O}_4 \cdot (2 + x)\text{H}_2\text{O}$ ) was the primary component, with quartz, calcite, and a trace of gypsum also present (weddellite was not observed in any of the crust samples). The lichen surface and thallus structures are shown in Figures 2 and 3, respectively.

### *Radiocarbon Ages and $\delta^{13}\text{C}_{\text{PDB}}$ of Whewellite*

Radiocarbon ages and stable carbon isotope data for the 14 rock crust samples are shown in Table 2. The ages range from  $730 \pm 80$  to  $5570 \pm 60$  yr B.P., with the oldest date from a geographically distinct site (41VV888) near the Devils River. The remainder of the  $^{14}\text{C}$  ages fall into four clusters when plotted in temporal profile (Fig. 4). In cases where samples had two strata, a comparison of ages obtained for the upper (128-7B and 129-1A) and corresponding lower (128-7D and 129-1B, respectively) strata indicate internal consistency with stratigraphic conformability. The ages of the oxalate layers associated with the prehistoric paints were also consistent with previously deduced pictograph ages. For example, sample 129-1B ( $3220 \pm 60$  yr B.P.) contained prehistoric paint expected to date between 2950 and 4200 yr B.P. based on the pictograph style. Also, sample 576-Ac ( $3020 \pm 70$  yr B.P.) was collected from the same site as two pictographs dated  $3000 \pm 70$  and  $3355 \pm 65$  yr B.P. (Russ *et al.*, 1992). Furthermore, sample 75-1 ( $1840 \pm 70$  yr B.P.) was taken from a site where the oxalate rock crust consistently overlies paints that are expected to date  $>2950$  yr B.P. (Russ *et al.*, 1992).

The results of the AMS calcium oxalate control samples, which were expected to have a fraction modern value of 1.341, ranged from  $1.3355 \pm 0.0072$  to  $1.3516 \pm 0.0076$ . These data show that the sample preparation did not have a measurable effect on the radiocarbon age of the crust samples.

The  $\delta^{13}\text{C}_{\text{PDB}}$  values range from  $-6.08$  to  $-13.70$ ‰ (Table 2). No apparent correlation exists between the stable carbon isotope composition and the  $^{14}\text{C}$  age, shelter type, distance from water, or thickness of crust.

## DISCUSSION

### *Origin of the Whewellite-Rich Crust*

The primary weathering occurring inside Lower Pecos rock shelters prior to the Holocene is thought to be limestone spalling induced by freeze-thaw cycles (Kochel, 1982, p. 268). Amelioration of the climate during the late Pleistocene/early Holocene allowed the limestone walls inside the shelters to stabilize (D. G. Robinson, personal communication, 1995), and they have remained stable despite xeric-mesic fluctuations in the middle to late Holocene. The presence of intact Pecos River style rock art in more than 250 rock art sites indicates that many shelter walls have remained stable since at least 2950 to 4200 yr B.P.

<sup>a</sup> Mineral identifications based on JCPDS nos. 20-321 for whewellite (wh), 33-311 for gypsum (gyp), 33-1161 for quartz (qtz), 24-27 for calcite (cal), and 17-541 for weddellite (wed).

The rock crust inside the shelters is composed of whewellite, gypsum, and clay, and covers limestone containing quartz. The gypsum results from efflorescence/subflorescence (Turpin, 1982, p. 197), processes that involve calcium and sulfate ions carried to the rock surface by water percolating through the substrate. Evaporation of the water at the rock surface causes gypsum to precipitate as layers and intrusions in the crust, and in the pores and fissures of the substrate (Winkler, 1975, pp. 117–119). The clay is likely derived from eolian matter adhering to the rock surfaces (e.g., Curtiss *et al.*, 1985).

The evidence shows that the whewellite was likely produced by a lichen such as *A. calcarea* or a similar species (Russ *et al.*, 1995). Whewellite microstructures in the crust are strikingly similar to features of *A. calcarea*, an epilithic lichen that occurs on limestone, produces calcium oxalate, inhabits cool or warm xeric environments, and does not contain rhizines (Poelt, 1973, p.619; Wadsten and Moberg, 1985). Because the paint layers below the crusts are not

disrupted, it is inferred that the lichen that produced the whewellite was epilithic and without rhizines.

Lichens are well known to produce calcium oxalate (Syers *et al.*, 1967; Wadsten and Moberg, 1985) that can form crusts on rock surfaces (Del Monte *et al.*, 1987). Moreover, they are known to colonize such special habitats with little or no precipitation, acquiring moisture from atmospheric water vapor (Lange, 1988). Although the pruina on the *A. calcarea* sample from the Lower Pecos is composed of weddellite, this mineral is metastable and decomposes to whewellite (Frey-Wyssling, 1981). Moreover, Ascaso *et al.* (1982) reported that lichens preferentially produce whewellite when on dry rock, and weddellite on rocks that are hydrated.

Fungi are also known to inhabit rocks in desert environments (Staley *et al.*, 1982) and can produce calcium oxalate when associated with various soils (Graustein *et al.*, 1977; Verrecchia, 1990; Verrecchia *et al.*, 1990). However, the relative amount of calcium oxalate in the crust is far greater than that of the clay; thus, eolian transport could not supply

**FIG. 3.** SEM photomicrographs of (A) whewellite microstructures in cross-sectional views of the crust; (B) magnified view of region indicated in 3A; and (C) cross-sectional view of the lichen *Aspiclia calcarea*.

the requisite organic matter necessary for fungi to produce the whewellite. Furthermore, studies of rock art dating (e.g., Ilger *et al.*, 1995) have demonstrated that the limestone in the Lower Pecos region has a low content of organic matter.

The  $\delta^{13}\text{C}_{\text{PDB}}$  values of the oxalate have a 7.62‰ range and are significantly higher than those reported for lichen thalli (Lange, 1988). This discrepancy could be due to the different metabolic pathways that produce thalli and exuded oxalate. For example, Rivera and Smith (1979) found that  $\delta^{13}\text{C}_{\text{PDB}}$  of calcium oxalate (primarily whewellite) from cacti in western Texas was approximately 5‰ higher than that of woody fibers from the same plants. If calcium oxalate from lichens is also enriched by 5‰ relative to the remainder of the organism, then the intact lichens that produced the oxalate in Table 2 would have had  $\delta^{13}\text{C}_{\text{PDB}}$  values ranging from  $-18.7$  to  $-12.6$ ‰. These values would be within the upper portion of the range reported for lichen thalli ( $-35$  to  $-14$ ‰; Lange and Ziegler, 1986). While the  $\delta^{13}\text{C}_{\text{PDB}}$  results could indicate some bicarbonate effect, as Lapeyrie (1988) demonstrated for fungi, this is highly unlikely because this would produce anomalously old radiocarbon dates that would not be consistent with the age of the exposed rock surfaces and the associated paints.

### *Paleoenvironmental Implications*

Many lichen species are known to occur within specific environmental regimes. Klappa (1979) recognized the far-reaching implications of understanding characteristic weathering features produced by past lichen activity for developing paleoclimate reconstructions. Danin *et al.* (1982; Danin, 1986, 1993) used lichen weathering features to develop a paleoclimate model for Israel, but the inability to date these features directly sometimes limits the accuracy of such reconstructions. From the evidence presented above, the whewellite in Lower Pecos rock crust is a biogenic residue produced by a specific lichen; thus, there is significant potential for obtaining accurate paleoclimate data.

Whewellite was found to be ubiquitous on surfaces in sheltered areas throughout the Lower Pecos (Russ *et al.*, 1995) and covers vast areas of limestone. This indicates that the lichen community must have flourished in this particular habitat. Since *A. calcarea* is a xeric lichen, the whewellite was likely produced primarily during dry periods, specifically when the substrate was dry. Under these conditions, the organism would obtain its requisite moisture by means of dew, fog, and water vapor, mechanisms used by a variety of desert lichens (Kappen, 1973; Lange, 1988). The two

major rivers converging in the Lower Pecos provide a source of water even during long periods of drought. Moreover, rock surfaces in shelters on which lichens grew can obtain and retain a great deal of condensation moisture, even under dry desert conditions (Winkler 1975, p. 102). The oxalate pruina would then benefit the lichens by retaining water and reducing the calcium concentration of the water on the rock surface (Wadsten and Moberg, 1985; Whitney and Arnot, 1987).

During wet periods, the vitality of the lichens would be severely reduced due to a variety of physiological reasons, including response to freezing water (Kappen, 1973, p. 328), an imbalance in water conditions that severely limits the virulence of either the fungi or algal components of the lichens (Kappen, 1973, p. 325), and inundation with water from the substrate that was saturated with calcium and sulfate. Thus, during mesic conditions the organism would be stressed, reducing growth and oxalate production, and gypsum would be deposited on the crust surface and in voids left by decaying lichen matter.

We suggest that  $^{14}\text{C}$  ages of the whewellite correspond to xeric climate regimes, while gaps in the data indicate mesic periods. Nine of the fourteen  $^{14}\text{C}$  ages correlate with dry climate episodes inferred by Johnson and Goode (1994) based on geomorphological, paleontological, and palynological data, mostly from the eastern Edwards Plateau of central Texas. Six of our data (clusters 3 and 4) fall within the Edwards Dry interval between about 4500 and 2500 yr B.P., while three of four data in cluster 1 fall within a brief dry interval between 1100 and 300 yr B.P. (Johnson and Goode,

1994, Fig. 2). However, Johnson and Goode (1994) indicate a mesic climate between about 2500 and 1100 yr B.P., whereas cluster 2 of our data occurs between 2080 and 1840

**FIG. 4.** Temporal profile of the  $^{14}\text{C}$  ages of oxalate crust along with paleoclimate reconstructions for central Texas.

yr B.P. Nordt *et al.* (1994; Boutton *et al.* 1994), however, predict local maximum paleotemperatures at 2000 and 1000 yr B.P. based on stable carbon isotope ratios of organic matter from paleosols and alluvial deposits in central Texas. These peak temperatures are in excellent agreement with dry climates predicted from clusters 1 and 2, whose ages average 1005 and 1970 yr B.P., respectively. However, Nordt *et al.* (1994) and Humphrey and Ferring (1994) predict low temperatures (and inferred wet climatic conditions) from about 4000 to 2500 yr B.P. Our cluster 3, which ranges from 3220 to 2730 yr B.P., implies a dry episode for the Lower Pecos during this period.

Bryant and Holloway's (1985) paleoclimate model for southwest Texas, based on palynological data from archaeological sites in the Lower Pecos, indicates that the region experienced a continuous drying trend during the late Holocene that was interrupted about 2500 yr B.P. by a brief mesic interlude. This brief wet episode correlates with a gap in our data from 2730 to 2080 yr B.P. Two other gaps in our data, from 1840 to 1330 yr B.P. and from 3990 to 3220 yr B.P., correspond to periods when the human population in the Lower Pecos was at a maximum (Turpin, 1990).

## CONCLUSIONS

Evidence indicates that dry limestone rock shelters in Lower Pecos canyons were an ideal niche for the desert lichen species *Aspicilia calcarea* during xeric climate episodes. We hypothesize that the virulence of the organism waxed and waned in response to shifts from dry to wet climate in the region. The lichen produced a calcium oxalate (whewellite) residue on the shelter walls during dry periods that can be radiocarbon dated to establish when the lichen flourished; thus, the oxalate serves as an indicator of past xeric climate regimes. Based on 14 radiocarbon ages of the whewellite, we infer wet-dry climate fluctuations during the late Holocene that are in good agreement with models established for other regions of Texas. Because our reconstruction is based on a completely independent mechanism—the vitality of a lichen—it should provide a useful check on paleoclimate models based on other evidence. Furthermore, the ubiquity of the whewellite rock crust in natural environments suggests that this technique may be a potentially valuable paleoclimate indicator of wide applicability.

The preliminary paleoclimate reconstruction proposed here suggests a ca. 1000-yr wet/dry climate cycle for the Lower Pecos. We emphasize, however, that this inference is dependent on two important assumptions: (1) that the lichens did not metabolize or incorporate carbon from the carbonate substrate during the production of the oxalate; this would cause anomalous  $^{14}\text{C}$  ages that are not representative of the time the lichens were viable; and (2) that deposition of the whewellite during two different arid climate episodes

can be distinguished based on sample stratigraphy; radiocarbon dates from samples in which multiple deposits of the oxalate are not discernable would not be representative of xeric episodes.

## ACKNOWLEDGMENTS

The authors thank S. Turpin, R. Ralph, F. Garcia, J. Skiles, and E. Brotherton for assistance in sample collection; K. Dowell for help with the lichen analysis; M. He and I. Perry for assistance with stable carbon isotope measurements; and J. Southon for AMS dating. We gratefully acknowledge J. Labadie and A. Watchman for helpful discussions and criticisms. We also thank V. Bryant and P. Bierman for reviewing this paper and providing helpful comments and criticisms that improved the manuscript. This research was supported by a Cottrell College Science Award of Research Corporation and grants from The National Center for Preservation Technology and Training and the Robert A. Welch Foundation.
